8 **Abstract**

9 A parameterization strategy for molecular models on the basis of force
10 fields is proposed, which allows a rapid development of models for small
11 molecules by using results from quantum mechanical (QM) *ab initio* calcu-
12 lations and thermodynamic data. The geometry of the molecular models
13 is specified according to the atom positions determined by QM energy
14 minimization. The electrostatic interactions are modeled by reducing the
15 electron density distribution to point dipoles and point quadrupoles lo-
16 cated in the center of mass of the molecules. Dispersive and repulsive
17 interactions are described by Lennard-Jones sites, for which the param-
18 eters are iteratively optimized to experimental vapor-liquid equilibrium
19 (VLE) data, i.e. vapor pressure, saturated liquid density, and enthalpy of
20 vaporization of the considered substance. The proposed modeling strat-
21 egy was applied to a sample set of ten molecules from different substance
22 classes. New molecular models are presented for iso-butane, cyclohexane,

23 formaldehyde, dimethyl ether, sulfur dioxide, dimethyl sulfide, thiophene,
24 hydrogen cyanide, acetonitrile, and nitromethane. Most of the models
25 are able to describe the experimental VLE data with deviations of a few
26 percent.

28 critical properties; iso-butane; cyclohexane; formaldehyde; dimethyl ether; sul-
29 fur dioxide; dimethyl sulfide; thiophene; hydrogen cyanide; acetonitrile; ni-
30 tromethane

1 Introduction

32 Molecular modeling and simulation is a progressive approach for describing
33 and predicting thermophysical properties of both pure substances and mixtures
34 of technical interest. Many authors have shown the excellent capabilities of
35 this molecular approach for different applications [1, 2]. Unfortunately, the
36 more widespread use of molecular methods for engineering applications is still
37 restricted by the scarcity of suitable molecular models.

38 For many substances, transferable molecular models have been developed,
39 i.e. force fields for classes of compounds like alkanes or alcohols. Thereby,
40 it is assumed that the parameters for functional groups are valid for different
41 molecular species. The main disadvantage of transferable models is that their
42 parameters were adjusted for the whole substance class and may not be optimal
43 for a specific substance. Furthermore, they do not cover substances outside the
44 modeled class. An overview and assessment of some commonly used transferable
45 potentials can be found in [3].

46 Molecular models that were optimized for specific substances are available
47 only for selected compounds and, particularly older ones, sometimes do not show
48 the desired quality. Therefore, from an engineering point of view, a method for
49 the rapid development of new molecular models for specific substances is of
50 great interest. Moreover, the molecular models should be accurate, simple,

51 and computationally efficient. In the present paper, a systematic strategy is
52 proposed to develop such models.

53 The present work is restricted to rigid, non-polarizable models for com-
54 paratively small molecules. The models have state-independent parameters
55 throughout. For computational efficiency, the united-atom approach is used,
56 i.e. hydrogen atoms bonded to carbon are not modeled explicitly. The proposed
57 strategy uses information determined by quantum mechanical (QM) *ab initio*
58 calculations to include physically sound molecular properties and to reduce the
59 number of adjustable parameters. A remaining subset of model parameters –
60 typically two to four – is subsequently optimized by adjustment to experimen-
61 tal data on vapor-liquid equilibria (VLE) of the pure substances. The aim is
62 to achieve deviations to experimental values for the vapor pressure, saturated
63 liquid density, and enthalpy of vaporization in the range from triple point to
64 critical point of below 5, 1, and 5%, respectively.

65 Such accurate models are known to have an excellent extrapolative and pre-
66 dictive power. This was recently shown, e.g., by the prediction of 17 different
67 thermophysical properties for ethylene oxide, covering phase equilibria, thermal,
68 caloric, transport properties, and surface tension [4], or for ammonia including
69 structural quantities [5].

70 Molecular models that were developed on the basis of QM calculations stand
71 between strictly *ab initio* models and fully empirical models. The present strat-
72 egy is based on the idea to include substantial *ab initio* information without giv-
73 ing up the freedom to reasonably optimize the model to important macroscopic
74 thermodynamic properties. Thus, for the modeling process some experimental
75 data is needed for optimization. All three chosen properties, mentioned above,
76 have the advantage to be well available for numerous engineering fluids and to
77 represent dominant features of the fluid state.

78 The parameters of a molecular model can be separated into three groups.
79 Firstly, geometric parameters specify the locations of the different interaction
80 sites of the molecular model. Secondly, electrostatic parameters define the in-

81 teractions of static polarities of the single molecules. And finally, dispersive
 82 and repulsive parameters determine the attraction by London forces and the
 83 repulsion by overlaps of the electronic orbitals. Here, the Lennard-Jones 12-6
 84 (LJ) potential [6, 7] was used to assure straightforward compatibility with the
 85 overwhelming majority of the molecular models in the literature.

86 To describe the intermolecular interactions, a varying number of LJ sites
 87 and superimposed ideal point dipoles and/or ideal linear point quadrupoles
 88 were used. Point dipoles or quadrupoles were employed for the description of
 89 the electrostatic interactions to reduce the computational effort significantly.
 90 A point dipole may, e.g. when a simulation program does not support this
 91 interaction site type, be approximated by two point charges $\pm q$ separated by
 92 a distance l . Limited to small l , one is free to choose this distance as long as
 93 $\mu = ql$ holds. Analogously, a point quadrupole can be approximated by three
 94 collinear point charges q , $-2q$, and q separated by l each, where $Q = 2ql^2$.

95 The total intermolecular interaction energy writes as

$$\begin{aligned}
 U = & \sum_{i=1}^{N-1} \sum_{j=i+1}^N \left\{ \sum_{a=1}^{S_i^{\text{LJ}}} \sum_{b=1}^{S_j^{\text{LJ}}} 4\epsilon_{ijab} \left[\left(\frac{\sigma_{ijab}}{r_{ijab}} \right)^{12} - \left(\frac{\sigma_{ijab}}{r_{ijab}} \right)^6 \right] + \right. \\
 & \left. \sum_{c=1}^{S_i^e} \sum_{d=1}^{S_j^e} \frac{1}{4\pi\epsilon_0} \left[\frac{\mu_{ic}\mu_{jd}}{r_{ijcd}^3} \cdot f_1(\boldsymbol{\omega}_i, \boldsymbol{\omega}_j) + \frac{\mu_{ic}Q_{jd} + Q_{ic}\mu_{jd}}{r_{ijcd}^4} \cdot f_2(\boldsymbol{\omega}_i, \boldsymbol{\omega}_j) + \frac{Q_{ic}Q_{jd}}{r_{ijcd}^5} \cdot f_3(\boldsymbol{\omega}_i, \boldsymbol{\omega}_j) \right] \right\},
 \end{aligned}
 \tag{1}$$

96 where r_{ijab} , ϵ_{ijab} , σ_{ijab} are the distance, the LJ energy parameter, and the
 97 LJ size parameter, respectively, for the pair-wise interaction between LJ site a
 98 on molecule i and LJ site b on molecule j . ϵ_0 is the permittivity of vacuum,
 99 whereas μ_{ic} and Q_{ic} denote the dipole moment and the quadrupole moment of
 100 the electrostatic interaction site c on molecule i , and so forth. $f_x(\boldsymbol{\omega}_i, \boldsymbol{\omega}_j)$ are
 101 expressions for the dependency of the electrostatic interactions on the orienta-
 102 tions $\boldsymbol{\omega}_i$ and $\boldsymbol{\omega}_j$ of the molecules i and j , cf. [8, 9]. Finally, the summation
 103 limits N , S_x^{LJ} , and S_x^e denote the number of molecules, the number of LJ sites,
 104 and the number of electrostatic sites, respectively.

Interactions between LJ sites of different type are determined by applying the standard Lorentz-Berthelot combining rules [10, 11]

$$\sigma_{ijab} = \frac{\sigma_{iaaa} + \sigma_{jjbb}}{2}, \quad (2)$$

and

$$\varepsilon_{ijab} = \sqrt{\varepsilon_{iaaa}\varepsilon_{jjbb}}. \quad (3)$$

2 Molecular properties from QM

In a recent publication, Sandler et al. [12] gives a brief overview on the use of QM for the calculation of thermophysical properties. By numerically solving Schrödinger’s equation, it is nowadays possible to calculate different molecular properties for technically relevant components in a quite standardized way. Many different QM codes are available for this task. For license reasons, the open source code GAMESS(US) [13] was used in the present work.

2.1 Geometry

All geometric data of the molecular models, i.e. bond lengths, angles, and dihedrals, were directly taken from QM calculations. Therefore, a geometry optimization, i.e. an energy minimization, was initially performed using GAMESS(US) [13]. The Hartree-Fock level of theory was applied with a relatively small (6-31G) basis set. Alternatively, density functional theory (DFT) methods, e.g. BLY3P, can be used, as they are known to give reasonable results for the molecular structure [14].

The resulting configuration of the atoms was taken without subsequent modification to specify the position of the LJ sites in space, except for the hydrogen atoms. As the united atom approach was used to obtain computationally efficient molecular models, the hydrogen atoms were modeled together with the carbon atom they are bonded to. For the methylene (CH_2) and methyl (CH_3) united atom sites, the LJ potential was located at the geometric mean of the nuclei, while the methine (CH) united atom site was located at 0.4 of the dis-

132 tance between carbon and hydrogen atom, cf. Figure 1. These empirical offsets
133 are in good agreement with the results of Ungerer et al. [15], which were found
134 by optimization of transferable molecular models for n-alkanes.

12.2 Electrostatics

136 Intermolecular electrostatic interactions mainly occur due to static polarities
137 of single molecules that can well be obtained by QM. Here, the Møller-Plesset
138 2 level was used that considers electron correlation in combination with the
139 polarizable 6-311G(d,p) basis set.

140 The purpose of the present work is the development of effective pair poten-
141 tials with a state-independent set of model parameters. Obviously, the electro-
142 static interactions are stronger in the liquid state than in the gaseous state due
143 to the higher density. Furthermore, the mutual polarization raises their mag-
144 nitude in the liquid. Thus, for the calculation of the electrostatic moments by
145 QM a liquid-like state should be considered. This was done here by placing the
146 molecule within a dielectric continuum and assigning the experimental dielectric
147 constant of the liquid to it, as in the COSMO method [16].

148 From the resulting electron density distribution for the small symmetric
149 molecules regarded here, ideal point dipoles and ideal linear point quadrupoles
150 were estimated by simple integration over the orbitals. Magnitudes and orien-
151 tations of these electrostatic interaction sites were used in the molecular models
152 without any modification.

153 For other, more complex molecules, more sophisticated methods like CHELP
154 [17], CHELPG [18], or the distributed multipole analysis [19] are available in
155 the literature. These methods adjust a set of partial charges or higher order
156 electrostatic sites to the electrostatic potential around the molecule calculated
157 by QM. Although they are able to reflect the electrostatic interactions with
158 higher accuracy, they are not considered here. They always yield a larger number
159 of interaction sites if they are not co-located with other sites and would thus
160 lead to computationally more expensive molecular models.

2.3 Dispersion and Repulsion

It would be highly desirable to also calculate the dispersive and repulsive interactions using *ab initio* methods as well. This approach was followed by different authors in the past, e.g. for neon [20, 21, 22, 23], argon [21, 23, 24], krypton [25], nitrogen [26], carbon dioxide [27], hydrogen chloride [28], acetone [29], methanol [29], acetylene [30], and methanethiol [31]. However, from an engineering point of view, this leads to difficulties.

For an estimation of dispersive and repulsive interactions at least two molecules must be taken into account. To properly scan the energy hyper surface, many QM calculations at different distances and orientations of the molecules have to be performed. As the dispersive, and partly also the repulsive, interactions are just a very small fraction of the total energy calculated by QM, highly accurate methods like coupled cluster (CC) with large basis sets or even extrapolations to the basis set limit must be used for this task [12].

Due to the fact that this is computationally too expensive for engineering purposes, we used the parameters for the dispersive and repulsive interactions for an initial model from similar sites of other molecular models. Some of these parameters were subsequently fitted in the optimization process to yield the correct VLE behavior of the modeled substance.

3 Optimization to VLE data

The optimization was performed using a Newton scheme as proposed by Stoll [32]. The applied method has many similarities with the one published by Ungerer et al. [33] and later on modified by Bourasseau et al. [34]. It relies on a least-square minimization of a weighted fitness function $\mathcal{F}$ that quantifies the deviations of simulation results from a given molecular model compared to experimental data. The weighted fitness function writes as

$$\mathcal{F} = \frac{1}{d} \sum_{i=1}^d \frac{1}{(\delta A_{i,\text{sim}})^2} (A_{i,\text{sim}}(\mathbf{M}_0) - A_{i,\text{exp}})^2, \quad (4)$$

wherein the n -dimensional vector $\mathbf{M}_0 = (m_{0,1}, \dots, m_{0,n})$ represents the set of n

189 model parameters $m_{0,1}, \dots, m_{0,n}$ to be optimized. The deviations of results from
 190 simulation $A_{i,\text{sim}}$ to experimental data $A_{i,\text{exp}}$ are weighted with the expected
 191 simulation uncertainties $\delta A_{i,\text{sim}}$. Equation (4) allows simultaneous adjustment
 192 of the model parameters to different thermophysical properties A_i (saturated
 193 liquid densities ρ' , vapor pressures p_σ , and enthalpies of vaporization Δh_v at
 194 various temperatures in the present work).

195 The unknown functional dependence of the property A_i on the model pa-
 196 rameters is approximated by a first order Taylor series developed in the vicinity
 197 of the initial parameter set $\mathbf{M}_0$

$$A_{i,\text{sim}}(\mathbf{M}_{\text{new}}) = A_{i,\text{sim}}(\mathbf{M}_0) + \sum_{j=1}^n \frac{\partial A_{i,\text{sim}}}{\partial m_j} \cdot (m_{\text{new},j} - m_{0,j}) . \quad (5)$$

199 Therein, the partial derivatives of A_i with respect to each model parameter m_j ,
 200 i.e. the sensitivities, are calculated from difference quotients

$$\frac{\partial A_{i,\text{sim}}}{\partial m_j} \approx \frac{A_{i,\text{sim}}(m_{0,1}, \dots, m_{0,j} + \Delta m_j, \dots, m_{0,n}) - A_{i,\text{sim}}(m_{0,1}, \dots, m_{0,j}, \dots, m_{0,n})}{\Delta m_j} . \quad (6)$$

202 Assuming a sound choice of the model parameter variations Δm_j , i.e. small
 203 enough to ensure linearity and large enough to yield differences in the simulation
 204 results significantly above the statistical uncertainties, this method allows a step-
 205 wise optimization of the molecular model by minimization of the fitness function
 206 $\mathcal{F}$. Experience shows that an optimized set of model parameters was usually
 207 found within a few iterative steps when starting from a reasonable initial model.

208 Correlations for vapor pressure, saturated liquid density, and enthalpy of
 209 vaporization, taken from the DIPPR database [35], were used as "experimental
 210 data" for model adjustment and evaluation. This was done even in cases where
 211 the correlation is based on no or only few true experimental data points, as the
 212 correlations were regarded best practice. The comparison between simulation
 213 results and experiment was done by applying fits to the simulation data accord-
 214 ing to Lotfi et al. [36]. The relative deviation between fit and correlation was
 215 calculated in steps of 1 K from 55 to 97% of the critical temperature and is
 216 denoted by "mean unsigned error" in the following.

217 Vapor-liquid equilibrium simulations were performed using the Grand Equi-
218 librium method by Vrabec et al. [37], technical simulation details are given in
219 the appendix.

220 **4 Molecular Models**

221 The selected ten molecules belong to different substance classes to show the
222 wide applicability of the proposed strategy. In the present work, we restricted
223 ourselves to small molecules, where the internal degrees of freedom may be
224 neglected. Thus, the molecular models are rigid, using the most stable configu-
225 ration determined by QM.

226 The optimized parameter sets of the new molecular models are summarized
227 in Table 1. Table 2 compares the critical properties from simulation to exper-
228 imental data. The critical properties from simulation were obtained through
229 fits to VLE simulation results as suggested by Lotfi et al. [36]. The estimated
230 uncertainties of critical temperature, critical density, and critical pressure from
231 simulation are 0.5, 2, and 2%, respectively. A very good agreement between sim-
232 ulation and experiment was reached, being predominantly within the combined
233 error bars.

234 In the following sections, substance specific details are briefly discussed.
235 Furthermore, references to alternative models from the literature are given and
236 the simulation results from the present models are compared to simulation data
237 from the literature where available. Numerical VLE simulation results are given
238 as Supplementary Material.

239 **4.1 Iso-Butane and Cyclohexane**

240 The branched alkane iso-butane and the cyclic alkane cyclohexane show only
241 very weak static polarities. Here, the main contributions to the intermolecular
242 interaction are dispersion and repulsion. The electrostatic interactions have
243 only a minor influence but should not be neglected completely.

244 In the literature different molecular models for iso-butane can be found,

245 which are mostly based on force fields for branched alkanes. The well-known
 246 OPLS force field by Jorgensen et al. is available in two versions for iso-butane,
 247 one using the united-atom approach [45] and one using an all-atom description
 248 [46]. Both OPLS force fields were optimized to liquid density and enthalpy of
 249 vaporization at 293 K only. The model of Poncela et al. [47] was adjusted
 250 to yield correct second virial coefficients. For a better applicability in a wider
 251 range of states, recent developments were optimized to experimental VLE data.
 252 Examples from this group are the force fields presented by Nath and de Pablo
 253 [48], Martin and Siepmann [49], Bourasseau et al. [50], or Chang and Sandler
 254 [51].

255 For the present model, four LJ sites, one for each methyl group and one
 256 for the methine group, were used to describe dispersion and repulsion of iso-
 257 butane. The polarity was modeled by a single (weak) dipole (0.1347 D) located
 258 in the center of mass. Orientation and magnitude of the dipole were taken from
 259 the QM calculation. For the initial model, the LJ parameters were taken from
 260 Ungerer et al. [15]. It was sufficient to adjust a single parameter, the offset
 261 distance of the methine group. It was optimized to 0.4 of the carbon-hydrogen
 262 distance, cf. Figure 1 and held constant subsequently. The parameters of the
 263 present model are given in Table 1.

264 Figures 2 to 4 show saturated densities, vapor pressure, and enthalpy of
 265 vaporization, respectively, from the present iso-butane model in comparison to
 266 experimental data [35]. Figure 5 shows a deviation plot between simulation and
 267 experimental data. In the deviation plot also simulation results from Martin
 268 and Siepmann, using their TraPPE force field, [49] and from Nath and de Pablo
 269 [48] are included. A very good agreement was obtained for the present model
 270 yielding mean unsigned errors in vapor pressure, saturated liquid density, and
 271 enthalpy of vaporization of 4.2, 0.6, and 1.8%, respectively, in the temperature
 272 range from 55 to 97% of the critical temperature, which is about 225 to 395 K.
 273 For vapor pressure, the present model yields significantly better results than
 274 the TraPPE force field, while no simulation data is available from Nath and

275 de Pablo for this property. For saturated liquid density, all three models yield
276 comparable results within 1% deviation to experimental data. No comparison
277 between the models was possible for enthalpy of vaporization due to missing
278 numerical data in [48, 49].

279 For cyclohexane different molecular models are available in the literature [52,
280 53, 54, 55] which all account for the internal degrees of freedom. Nevertheless,
281 the present cyclohexane model was assumed to be rigid and in its most stable
282 configuration, i.e. the saddle shape. The molecular model consists of six LJ
283 sites, one for each methylene group. The static polarity was modeled by a
284 single quadrupole parameterized according to QM. The two LJ parameters for
285 methylene were optimized to experimental VLE data. The parameters of the
286 present model are given in Table 1.

287 Figures 2 to 4 again show present VLE simulation results in comparison to
288 experimental data for cyclohexane. Figure 6 shows the deviation plot including
289 simulation results from Bourasseau et al. [50]. The mean unsigned errors in
290 vapor pressure, saturated liquid density, and enthalpy of vaporization for the
291 present model are 0.9, 0.5, and 5.6%, respectively. Simulation results for the
292 enthalpy of vaporization show systematic relative deviations towards the critical
293 point, while the absolute deviation is below 2.5 kJ/mol.

294 Compared to the model of Bourasseau et al. improvements in the descrip-
295 tion of the saturated liquid density were achieved. The simulation results for
296 vapor pressure agree within their assumed simulation uncertainties which were
297 not reported by Bourasseau et al. An interesting point is that both molecular
298 models yield the same deviations from experimental data on the enthalpy of
299 vaporization, while the DIPPR database reports true experimental data up to
300 $0.97T_c$. For all other molecular models for cyclohexane mentioned above, no nu-
301 merical VLE simulation data is reported in the literature. Thus, no comparison
302 is made here.

4.2 Formaldehyde and Dimethyl Ether

The present molecular model for formaldehyde consists of two LJ sites, one for the oxygen atom and one for the methylene group, as well as one dipole. The dipole is located in the center of mass and its moment was specified according to QM results, cf. Table 1. All four LJ parameters were adjusted to experimental VLE data and are given in Table 1.

Figures 7 to 8 compare simulation results and experimental VLE data for formaldehyde, Figure 9 shows the relative deviations. Mean unsigned errors in vapor pressure, saturated liquid density, and enthalpy of vaporization are 4.3, 0.9, and 8.4%, respectively.

Note that, in contrast to iso-butane or cyclohexane, the available experimental data base is very weak here. In fact, for vapor pressure only a single data set from the year 1935 [56] is available. For saturated liquid density and enthalpy of vaporization, respectively, a single data point at 254 K is “accepted” by the DIPPR database [35]. Thus, no further optimization of the molecular model was attempted although the desired quality seems not to be fully reached. Hermida-Raón and Ríos [57] published a molecular model based on QM calculations of formaldehyde dimers and trimers. They applied their model to liquid phase simulations but report no results on VLE properties. Thus, no comparison is presented here.

Dimethyl ether was modeled with three LJ sites in the present work, one for the oxygen atom and one for each methyl group. A dipole was located in the center of mass and oriented along the symmetry axis of the molecule, where the dipole moment was again taken from QM calculation. For an initial model, the same LJ parameters of the methyl groups were taken as for the iso-butane model, i.e. those by Ungerer et al. [15]. An adjustment of the two LJ parameters of the oxygen site was sufficient to reach the desired quality. Alternative models for dimethyl ether are given in [58, 59, 60, 61].

The simulation results for the present model of dimethyl ether in comparison

332 to the experimental VLE data are shown in Figures 2 to 4. Figure 10 shows the
333 relative deviations between simulation and experiment also including simulation
334 results from Stubbs et al. [60] and very recent results from Ketko and Potoff [61].
335 For dimethyl ether a good experimental data base is available for optimization
336 of the molecular model. The simulation data of the present model is in very
337 good agreement with the correlations of experimental data. The mean unsigned
338 errors in vapor pressure, saturated liquid density, and enthalpy of vaporization
339 are 2.6, 0.4, and 1.0%, respectively.

340 For vapor pressure, both molecular models specifically adjusted to dimethyl
341 ether, i.e. the present model and the model by Ketko and Potoff, yield better re-
342 sults than the transferable molecular model by Stubbs et al., while for saturated
343 density all models perform similarly. For enthalpy of vaporization, the present
344 model and the model by Ketko and Potoff also yield comparable results. Note
345 that the parameters for the electrostatic interactions of the model by Ketko and
346 Potoff were adjusted to experimental VLE data as well.

347 It can be summarized that the model by Ketko and Potoff [61] and the
348 present dimethyl ether model are of similar quality and outperform the trans-
349 ferable model by Stubbs et al. [60]. While Ketko and Potoff adjusted four
350 LJ parameters and the point charge magnitudes for their electrostatic inter-
351 actions, following the proposed modeling strategy an optimization of only two
352 Lennard-Jones parameters was sufficient to reach the same quality.

34.3 Sulfur Dioxide, Dimethyl Sulfide, and Thiophene

354 For sulfur dioxide, a molecular model was published by Sokolić et al. [62,
355 63] which was optimized to total energy and pressure in the liquid state. It
356 was recently reviewed by Ribeiro [64]. Alternatively, the commercial force field
357 COMPASS [65] reports parameters for sulfur dioxide.

358 For the present molecular model, the intermolecular interactions of sulfur
359 dioxide were modeled with three LJ sites, i.e. one per atom, plus one dipole and
360 one quadrupole. The electrostatic sites are located in the center of mass and

parameterized according to the results of QM calculation. The four parameters of the LJ sites, i.e. σ_S , ϵ_S , σ_O , and ϵ_O , were adjusted to experimental VLE data. All parameters of the molecular model are given in Table 1.

Present simulation results for sulfur dioxide are compared to experimental VLE data in Figures 11 to 13. Figure 9 shows the relative deviations between simulation and experiment for the present model, while no numerical VLE simulation data for sulfur dioxide from other authors was available to us. Mean unsigned errors in vapor pressure, saturated liquid density, and enthalpy of vaporization are 4.0, 0.9, and 1.6%, respectively. The good experimental data base, with more than 60 individual experimental VLE data points, allows a thorough optimization of the molecular model to the desired quality.

Literature models for dimethyl sulfide are given in [66, 67, 68]. The present dimethyl sulfide model consists of three LJ sites, one for the sulfur atom and one for each methyl group. The electrostatic interactions are modeled by one dipole and two quadrupoles oriented perpendicularly to each other. This description of the electrostatics was chosen, as QM yields a charge distribution, which can not properly be described with a lower number of electrostatic sites. The LJ parameters of the methyl groups were assumed to be the same as for iso-butane and dimethyl oxide, while the parameters of the sulfur group were adjusted to experimental VLE data.

Figures 11 to 13 show the present simulation results for dimethyl sulfide in comparison to experimental VLE data. Figure 14 shows the relative deviations between simulation and experiment for the present model and for the model of Lubna et al. [68]. Note that simulation results on enthalpy of vaporization were not included in [68]. For the present model of dimethyl sulfide, mean unsigned errors in vapor pressure, saturated liquid density, and enthalpy of vaporization are 4.0, 0.7, and 3.8%, respectively. Particularly the vapor pressure is better described than by the model of Lubna et al.

Also thiophene was described in the present work by a rigid model in its most stable conformation, as for cyclohexane. Five LJ sites, one for each of the

391 four methylene groups and one for the sulfur atom, as well as one dipole and
 392 one quadrupole were used. The electrostatic parameters were directly passed
 393 on from QM. A total of four LJ parameters, i.e. σ_{CH_2} , $\varepsilon_{\text{CH}_2}$, σ_{S} , and ε_{S} ,
 394 were adjusted to experimental VLE data. The optimized parameters are given
 395 in Table 1. Alternative molecular models for thiophene can be found in the
 396 literature [68, 69, 70]

397 Figures 11 to 13 compare simulation results to experimental VLE data for
 398 thiophene, while the relative deviations are shown in Figure 15. In the deviation
 399 plot also simulation results from Lubna et al. [68], Juárez-Guerra et al. [69],
 400 and Pérez-Pellitero et al. [70] are included. Mean unsigned errors of the present
 401 model in vapor pressure, saturated liquid density, and enthalpy of vaporization
 402 are 3.8, 1.2, and 3.2%, respectively.

403 The thiophene model by Juárez-Guerra et al. [69] shows significant devia-
 404 tions in both vapor pressure and saturated liquid density while no simulation re-
 405 sults for the enthalpy of vaporization were given by the authors. The anisotropic
 406 united atoms (AUA) potential by Pérez-Pellitero et al. [70] overpredicts the va-
 407 por pressure over the complete temperature range by up to 20%. Simulation
 408 results for saturated liquid density and enthalpy of vaporization are in very good
 409 agreement with the DIPPR correlation for low temperatures but give noticeably
 410 higher values than the DIPPR correlation for temperatures above $0.7T_c$. The
 411 TraPPE force field by Lubna et al. [68] yields vapor pressure results that agree
 412 very well with the DIPPR correlation and the simulation results within their
 413 scatter. Saturated densities are higher than the correlation towards the critical
 414 point for all four molecular models. For enthalpy of vaporization no numerical
 415 data were given by Lubna et al.

416 It should be noted that for thiophene experimental vapor pressure data is
 417 available for temperatures up to around $0.9 T_c$, experimental saturated liquid
 418 densities and enthalpies of vaporization are only available up to approximately
 419 $0.63 T_c$. Thus, an assessment of the different molecular models regarding density
 420 and enthalpy of vaporization above $0.7 T_c$ on the basis of the DIPPR correlations

421 is questionable.

4.4 Hydrogen Cyanide, Acetonitrile, and Nitromethane

423 Hydrogen cyanide was modeled in the present work with two LJ sites, one
424 for the methine group and one for the nitrogen atom. Electrostatic interactions
425 were modeled by one dipole and one quadrupole oriented along the symmetry
426 axis, where the parameters were passed on from QM. All four LJ parameters
427 were adjusted to experimental VLE data. The optimized parameters can be
428 found in Table 1. For hydrogen cyanide no other molecular models were found
429 in the literature.

430 Figures 11 to 13 compare simulation results and experimental VLE data for
431 hydrogen cyanide. Figure 9 shows the relative deviations. Unfortunately, the
432 DIPPR database [35] contains no true experimental data on the enthalpy of
433 vaporization for hydrogen cyanide. Consequently, in the optimization process,
434 only minor attention was paid to the enthalpy of vaporization. Mean unsigned
435 errors in vapor pressure, saturated liquid density, and enthalpy of vaporization
436 are nominally 7.2, 1.0, and 12.2%, respectively.

437 Several molecular models for acetonitrile are available in the literature. Jor-
438 gensen and Briggs [71], Price et al. [77], Guárdia et al. [72], and Nikitin and
439 Lyubartsev [73] present models that were optimized to the liquid density and
440 enthalpy of vaporization at 293 K. Hloucha and Deiters [74] give a polarizable
441 molecular model for simulations in the liquid state while Hloucha et al. [29]
442 published a model that is based on *ab initio* calculations. Finally, Wick et al.
443 [78] proposed an extension of their TraPPE force field that was optimized to
444 VLE data to cover acetonitrile.

445 In the present work, acetonitrile was modeled using three LJ sites, one for the
446 methyl group, one for the central carbon atom, and one for the nitrogen atom.
447 The electrostatic interactions were modeled by one dipole and one quadrupole,
448 located in the center of mass and parameterized strictly according to QM results.
449 The parameters of the LJ sites of the methyl group and the nitrogen atom were

adjusted to experimental VLE data. The LJ parameters of the central carbon atom were taken from unpublished work on carbon dioxide and excluded from optimization, only a very weak sensitivity of the VLE simulation results on these parameters was found. All parameters of the molecular model are given in Table 1.

Simulation results for acetonitrile are compared to experimental VLE data in Figures 7 to 8. The relative deviations between simulation and experiment are shown in Figure 16 next to results of the OPLS-UA force field by Jorgensen and Briggs [71] and the TraPPE force field by Wick et al., which were reported for both models in [78]. Despite the good experimental data base, the desired quality was not achieved by the present optimization. Only a fair description of the experimental VLE was reached. Mean unsigned errors in vapor pressure, saturated liquid density, and enthalpy of vaporization are 19.7, 0.9, and 5.4%, respectively.

The large relative deviations in vapor pressure result from systematic underestimations at low temperatures. In this region also difficulties were encountered in the simulative calculation of the chemical potential in the liquid phase to determine the phase equilibrium. This was even the case when the more sophisticated gradual insertion method [79] was used, as described in the appendix in greater detail.

The OPLS-UA force field by Jorgensen and Briggs [71] significantly overestimates the vapor pressure of acetonitrile and shows deviations in the saturated liquid density up to 4%, cf. Figure 16. Simulation results for vapor pressure obtained with the TraPPE force field by Wick et al. [78] show a very good agreement with the DIPPR correlation, while the saturated density is slightly overpredicted towards the critical point. No comparison of the literature models for acetonitrile is possible regarding the enthalpy of vaporization due to the lack of numerical simulation results.

The present molecular model for nitromethane consists of four LJ sites, one for the methyl group, one for the nitrogen atom, and one for the two oxygen

atoms each. The electrostatic interactions were modeled by one dipole and one quadrupole oriented along the symmetry axis, where the parameters were specified according to QM results. All six LJ parameters were adjusted to experimental VLE data. Alternative models are available in the literature [75, 76, 77, 78].

Figures 11 to 13 compare the present simulation results for nitromethane with experimental VLE data. Figure 17 shows the relative deviations obtained with the present model, the OPLS-AA force field by Price et al. [77], and the TraPPE force field by Wick et al. [78]. For the present model of nitromethane, mean unsigned errors in vapor pressure, saturated liquid density, and enthalpy of vaporization are 18.7, 0.2, and 7.0%, respectively. Again, a systematic underprediction of the vapor pressure at low temperatures was found, leading to the high relative deviations, as for acetonitrile.

The OPLS-AA force field overpredicts the vapor pressure by about 80% and underpredicts the saturated liquid density by up to 6%. The TraPPE force field of Wick et al. that was optimized to experimental VLE data, yields very good results in vapor pressure for low temperatures while the result for the highest simulated temperature deviates by +34% from the DIPPR correlation. Regarding saturated liquid density, strong scatter and large statistical uncertainties of the simulation results are observed for both literature models.

5 Conclusion

A strategy was proposed for the rapid development of molecular models for engineering applications. The strategy relies on results from QM *ab initio* calculations to include physically sound molecular properties and to reduce the number of adjustable parameters. Dispersive and repulsive interactions were modeled by LJ sites. Thus, the LJ interaction sites were located according to atom positions obtained by QM energy minimization on Hartree-Fock level. For the parameterization of the electrostatic interactions, QM calculations were performed using the Møller-Plesset 2 level of theory and the COSMO method.

509 The resulting electron density distribution was reduced to ideal point dipoles
510 and ideal linear point quadrupoles located in the center of mass. The moments
511 and orientations of the dipoles and quadrupoles were passed on to the molecular
512 models without any modification.

513 A united-atom approach was used for methine, methylene, and methyl groups
514 to reduce the total number of interaction sites. The parameters of the LJ sites
515 were initially taken from similar sites of other molecular models and were sub-
516 sequently optimized to reproduce experimental VLE data, i.e. vapor pressure,
517 saturated liquid density, and enthalpy of vaporization. It was aimed to achieve
518 deviations between simulation and experiment of below 5, 1, and 5% in vapor
519 pressure, saturated liquid density, and enthalpy of vaporization, respectively.

520 The new modeling strategy was successfully applied to ten molecules from
521 different substances classes, i.e. iso-butane, cyclohexane, formaldehyde, dimethyl
522 ether, sulfur dioxide, dimethyl sulfide, thiophene, hydrogen cyanide, acetoni-
523 trile, and nitromethane. Simulation results for the different substances agree
524 well with correlations of experimental data taken from the DIPPR database
525 [35], with noticeable deviations in the vapor pressure at low temperatures for
526 acetonitrile and nitromethane.

527 For the two elongated molecules acetonitrile and nitromethane, the reduction
528 of the electrostatic interactions to sites located in the center of mass seems to be
529 an over-simplification, as the optimization of the molecular models was not fully
530 successful. Also an adjustment of the electrostatic parameters, while keeping
531 the ratio of the polar moments constant (not reported here in detail), did not
532 yield significant improvements in the quality of the molecular models. A further
533 study, e.g. using two or more spatially distributed electrostatic sites, is beyond
534 the scope of this paper.

535 For all other molecules a significant improvement compared to available
536 molecular models from the literature was achieved. Through an optimization
537 to substance specific experimental VLE data, a very good description of the
538 phase equilibria was obtained. Furthermore, in case of dimethyl ether it was

shown that with the proposed modeling strategy it was possible to reach the same model quality by optimization of just two model parameters compared to five optimized parameters for the model by Ketko and Potoff [61].

Acknowledgment

The authors gratefully acknowledge financial support by Deutsche Forschungsgemeinschaft, Schwerpunktprogramm 1155 "Molecular Modeling and Simulation in Process Engineering". The simulations were performed on the national super computer NEC SX-8 at the High Performance Computing Center Stuttgart (HLRS) under the grant MMHBF and on the HP XC6000 super computer at the Steinbuch Centre for Computing, Karlsruhe under the grant MMSTP.

The authors want to thank Inga Utz for her modeling work on the sulfur and nitrogen containing compounds.

Appendix

The Grand Equilibrium method [37] was used to calculate VLE data at seven to thirteen temperatures from 50 to 97% of the critical temperature during the optimization process. For the liquid, molecular dynamics simulations were performed in the isobaric-isothermal (NpT) ensemble using isokinetic velocity scaling [8] and Anderson's barostat [80]. There, the number of molecules was 864 throughout and the time step was 1 to 3 fs depending on the molecular weight and the magnitude of the intermolecular interactions. The initial configuration was a face centered cubic lattice, the fluid was equilibrated over 25 000 time steps with the first 5 000 time steps in the canonical (NVT) ensemble. The production run time span was 150 000 to 200 000 time steps with a membrane mass of 10^9 kg/m⁴. Widom's insertion method [81] was used to calculate the chemical potential by inserting up to 4 000 test molecules every production time step.

In cases where Widom's insertion method yielded large statistical uncertainties for the chemical potential, i.e. at high densities for strongly interacting

567 molecules, Monte Carlo simulations were performed in the NpT ensemble for
 568 the liquid. Then, the chemical potential was calculated by the gradual inser-
 569 tion method [82, 79]. The number of molecules was 500. Starting from a face
 570 centered cubic lattice, 15 000 Monte Carlo cycles were performed for equilibra-
 571 tion and 50 000 for production, each cycle containing 500 translation moves,
 572 500 rotation moves, and 1 volume move. Every 50 cycles, 5000 fluctuating
 573 state change moves, 5000 fluctuating particle translation/rotation moves, and
 574 25000 biased particle translation/rotation moves were performed, to determine
 575 the chemical potential. These computationally demanding simulations yield the
 576 chemical potential in dense and strong interacting liquids with high accuracy,
 577 leading to reasonable uncertainties in the VLE.

578 For the corresponding vapor, Monte Carlo simulations in the pseudo- μVT
 579 ensemble were performed. The simulation volume was adjusted to lead to an
 580 average number of 500 molecules in the vapor phase. After 1 000 initial NVT
 581 Monte Carlo cycles, starting from a face centered cubic lattice, 10 000 equi-
 582 libration cycles in the pseudo- μVT ensemble were performed. The length of
 583 the production run was 50 000 cycles. One cycle is defined here to be a num-
 584 ber of attempts to displace and rotate molecules equal to the actual number of
 585 molecules plus three insertion and three deletion attempts.

586 The cut-off radius was set to 17.5 Å throughout and a center of mass cut-off
 587 scheme was employed. Lennard-Jones long-range interactions beyond the cut-
 588 off radius were corrected employing angle averaging as proposed by Lustig [83].
 589 Electrostatic interactions were approximated by a resulting molecular dipole
 590 and corrected using the reaction field method [8]. Statistical uncertainties in
 591 the simulated values were estimated by a block averaging method [84].

TABLE 1: Parameters of the new molecular models. Lennard-Jones interaction sites are denoted by the modeled atoms (in boldface) with an additional bonding partner if necessary. Electrostatic interaction sites are denoted by dipole or quadrupole, respectively. Coordinates are given with respect to the center of mass in a principal axes system. Orientations of the electrostatic sites are defined in standard Euler angles, where φ is the azimuthal angle with respect to the $x - z$ plane and θ is the inclination angle with respect to the z axis.
